1 Handling data with pandas

1.1 Motivation

So far, we have encountered NumPy arrays as the only way to store numerical data (we mostly ignored the built-in contains provided directly in Python).

However, while NumPy arrays are great for storing homogenous data which does not have any particular structure, they are somewhat limited when we want to use them for high-level data analysis.

For example, we usually want to process data sets with

- 1. several variables
- 2. multiple observations, which need not be identical across variables (imagine we have some missing values)
- 3. non-homogenous data types: for examples, names need to be stored as strings, birthdays as dates and income as a floating-point number.

While NumPy can in principle handle such situations, it puts all the burden on the user. Most users would prefer to not have to deal with such low-level details.

Imagine we want to store names, birth dates and annual income for two persons:

Name	Date of birth	Income
Alice	1985-01-01	30,000
Bob	1997-05-12	

No income was reported for Bob, so it's missing. With NumPy, we could do this as follows:

```
[1]: import numpy as np
from datetime import date

date1 = date(1985, 1, 1)  # birth date for Alice
date2 = date(1997, 5, 12)  # birth date for Bob
```

While we can create such arrays, they are almost useless for data analysis, in particular since everything is stored as a generic object.

• To be fair, NumPy offers an alternative array type called "record" or "structured" array which can handle fields of different data types, but the pandas library offers much more beyond that, so there is little reason to use it.

Pandas was created to offer more versatile data structures that are straightforward to use for storing, manipulating and analysing heterogeneous data:

- 1. Data is clearly organised in variables and observations, similar to econometrics programs such as Stata.
- 2. Each variable is permitted to have a different data type.
- 3. We can use *labels* to select observations, instead of having to use a linear numerical index as with NumPy.

We could, for example, index a data set using National Insurance Numbers.

4. Pandas offers many convenient data aggregation and reduction routines that can be applied to subsets of data.

For example, we can easily group observations by city and compute average incomes.

5. Pandas also offers many convenient data import / export functions that go beyond what's in NumPy.

Should we be using pandas at all times, then? No!

- For low-level tasks where performance is essential, use NumPy.
- For homogenous data without any particular data structure, use NumPy.
- On the other hand, if data is heterogeneous, needs to be imported from an external data source and cleaned or transformed before performing computations, use pandas.

There are numerous tutorials on pandas on the internet, so we will keep this unit short and illustrate only the main concepts. Useful references to additional material include:

- The official user guide.
- The official pandas cheat sheet which nicely illustrates the most frequently used operations.
- The official API reference with details on every pandas object and function.
- There are numerous tutorials (including videos) available on the internet. See here for a list.

1.2 Creating pandas data structures

Pandas has two main data structures:

- 1. Series represents observations of a single variable.
- 2. DataFrame is a container for several variables. You can think of each individual column of a DataFrame as a Series.

The easiest way to get a Series or DataFrame is to create them from pre-existing data.

To access pandas data structures and routines, we need to import them first. The near-universal convention is to make pandas available using the name pd:

```
import pandas as pd
```

Examples:

We can create a DataFrame from a NumPy array:

```
import numpy as np
import pandas as pd  # universal convention: import using pd
from numpy.random import default_rng

# Draw normally distributed data
rng = default_rng(123)
data = rng.normal(size=(10,3))

# Create pandas DataFrame
varnames = ['A', 'B', 'C']
pd.DataFrame(data, columns=varnames)
```

```
[2]: A B C
0 -0.989121 -0.367787 1.287925
1 0.193974 0.920231 0.577104
2 -0.636464 0.541952 -0.316595
3 -0.322389 0.097167 -1.525930
4 1.192166 -0.671090 1.000269
5 0.136321 1.532033 -0.659969
6 -0.311795 0.337769 -2.207471
7 0.827921 1.541630 1.126807
8 0.754770 -0.145978 1.281902
9 1.074031 0.392621 0.005114
```

This code creates a DataFrame of three variables called A, B and C with 10 observations each.

Alternatively, we can create a DataFrame from non-homogenous data as follows:

```
[3]: # Names (strings)
    names = ['Alice', 'Bob']

# Birth dates (datetime objects)
    bdates = pd.to_datetime(['1985-01-01', '1997-05-12'])

# Incomes (floats)
    incomes = np.array([35000, np.nan]) # code missing income as NaN

# create DataFrame from dictionary
    pd.DataFrame({'Name': names, 'Birthdate': bdates, 'Income': incomes})
[31: Name Birthdate Income
```

```
[3]: Name Birthdate Income
0 Alice 1985-01-01 35000.0
1 Bob 1997-05-12 NaN
```

If data types differ across columns, as in the above example, it is often convenient to create the DataFrame by passing a dictionary as an argument, where each key contains a column name and each corresponding value the data for that variable.

1.3 Viewing data

With large data sets, you hardly ever want to print the entire <code>DataFrame</code>. Pandas by default limits the amount of data shown. You can use the <code>head()</code> and <code>tail()</code> methods to explicitly display a specific number of rows from the top or the end of a <code>DataFrame</code>.

To illustrate, we use a data set of a few UK universities that contains their name, number of students and budget in million pounds (both from Wikipedia), and their Times Higher Education (THE) ranking.

We can read in the data stored in universities.csv and display the first three rows like this:

```
[4]: import pandas as pd
     # Load sample data set of UK universities
     df = pd.read_csv('../data/universities.csv', sep=';')
     df.head(3)
                 # show first three rows
                    Institution
                                 Country Founded Students Budget
                                                                   Rank
[4]:
          University of Glasgow Scotland
                                          1451 30805
                                                           626.5
                                                                     92
     1
        University of Edinburgh Scotland
                                            1583
                                                     34275 1102.0
                                                                     30
                                                           251.2
     2 University of St Andrews Scotland
                                            1413
                                                     8984
                                                                    201
[5]: df.tail(3)
                    # show last three rows
[5]:
                       Institution
                                           Country Founded Students Budget

         301
         200
     21
```

To quickly compute some descriptive statistics for the *numerical* variables in the <code>DataFrame</code>, we use <code>describe()</code>:

```
[6]: df.describe()
               Founded
                           Students
                                         Budget
                                                      Rank
[6]:
     count.
            23.000000
                          23.000000 22.000000
                                                23,000000
    mean 1745.652174 24106.782609 768.609091 124.739130
     std

    min
           1096.000000 8984.000000 113.300000
                                                  1.000000
     25%
           1589.000000 18776.500000 340.850000
                                                 32.500000
     50%
           1826.000000 23247.000000
                                    643.750000 107.000000
     75%
           1941.500000 30801.500000 1023.500000 195.500000
           2004.000000 41180.000000 2450.000000 401.000000
    max
```

To see low-level information about the data type used in each column, we call info():

```
[7]: df.info()
    <class 'pandas.core.frame.DataFrame'>
    RangeIndex: 23 entries, 0 to 22
    Data columns (total 6 columns):
                   Non-Null Count Dtype
     # Column
                     -----
     0
         Institution 23 non-null
                                     object
     1
         Country 23 non-null
                                     object
     2
         Founded
                     23 non-null
                                     int64
                     23 non-null
     3
         Students
                                     int64
         Budget
                     22 non-null
                                     float64
         Rank
                     23 non-null
                                     int64
    dtypes: float64(1), int64(3), object(2)
    memory usage: 1.2+ KB
```

Note that pandas automatically discards missing information in computations. For example, the budget for Swansea University is missing, and this observation is therefore dropped when computing descriptive statistics.

1.4 Indexing

Pandas supports two types of indexing:

- 1. Indexing by position. This is basically identical indexing of other Python and NumPy containers.
- 2. Indexing by label, ie. by the values assigned to the row or column index. These labels need not be integers in increasing order, as is the case for NumPy.

Pandas indexing is performed either by using brackets [], or by using .loc[] for label indexing, or .iloc[] for position indexing.

Indexing via [] can be somewhat confusing:

- specifying df['name'] returns the column name as a Series object.
- On the other hand, specifying a range such as df[5:10] returns the *rows* associated with the *positions* 5,...,9.

Examples:

10

```
[8]: import pandas as pd
     # Load sample data set of UK universities
     df = pd.read_csv('../data/universities.csv', sep=';')
     df['Institution']
                                     # select a single column
[8]: 0

                Swansea University 251
```

To return the rows at positions 1, 2 and 3 we use

Pandas follows the Python convention that indices are 0-based, and the endpoint of a slice is not included.

1.4.1 Selection by label

Pandas uses *labels* to index and align data. These can be integer values starting at 0 with increments of 1 for each additional element, but they need not be.

For example, we can replace the row index and use the labels a, b, c, ... instead of integers as follows:

```
[11]: import pandas as pd
       df = pd.read_csv('../data/universities.csv', sep=';')
       # Map list of integers to lower-case roman letters
       index = [chr(97+i) for i in df.index.values]
       index
[11]: ['a',
        'b',
        'c',
        'd',
        'e',
        'f',
        'g',
        'h',
        'i',
        'j',
        'k',
        '1',
        'm',
        'n',
        '0',
        'p',
        'q',
        'r',

```

To add to the confusion, note that when specifying a range in terms of labels, the last element is included!

To more clearly distinguish between selection by label and by position, pandas provides the .loc[] and .iloc[] methods of indexing. To make your intention obvious, you should therefore adhere to the following rules:

- 1. Use df['name'] only to select *columns* and nothing else.
- 2. Use .loc[] to select by label.
- 3. Use .iloc[] to select by position.

To illustrate, using .loc[] unambiguously indexes by label:

With .loc[] we can even perform slicing on column names, which is not possible with the simpler df[] syntax:

This includes all the columns between Students and Rank, where the latter is again included since we are slicing by label.

Trying to pass in positional arguments will return an error if the index does not happen to be of type integer and the given values are actual labels:

```
[15]: df.loc[0:4]
```

```

                                                                              301
      11
```

Indexing via .loc[] supports a few more types of arguments, see the official documentation for details.

1.4.2 Selection by position

Conversely, if we want to select items exclusively by their position and ignore their labels, we use .iloc[]:

Again, .iloc[] supports a multitude of other arguments, including boolean arrays. See the official documentation for details.

1.5 Aggregation and reduction

1.5.1 Working with entire DataFrames

The simplest way to perform data reduction is to invoke the desired routine on the entire DataFrame:

Methods such as mean () are by default applied column-wise to each numerical column.

One big advantage over NumPy is that missing values (represented by np.nan) are automatically ignored:

```
[19]: # Set Aberdeen's THE ranking to missing
df.loc[df['Institution'] == 'University of Aberdeen', 'Rank'] = np.nan
df.loc[df['Institution'] == 'University of Aberdeen']
```

```
[19]:
                                 Country Founded Students Budget
                   Institution
      3 University of Aberdeen Scotland
                                           1495
                                                   14775
                                                             219.5
                                                                     NaN
[20]: # mean() automatically drops missing observations
      df.mean()
[20]: Founded
                  1745.652174
      Students
                 24106.782609
      Budget
                   768.609091
                   122.318182
      Rank
      dtype: float64
```

1.5.2 Splitting and grouping

Applying aggregation functions to the entire DataFrame is similar to what we can do with NumPy. The added flexibility of pandas becomes obvious once we want to apply these functions to subsets of data, ie. groups, which we can define based on values or index labels.

For example, we can easily group our university data by country:

```
[21]: import pandas as pd

df = pd.read_csv('../data/universities.csv', sep=';')

groups = df.groupby(['Country'])
```

Here groups is a special pandas objects which can be subsequently be used to process group-specific data. To compute the group-wise averages, we can simply run

```
[22]: groups.mean()
                           Founded
                                       Students
                                                      Budget
                                                                   Rank
[22]:
      Country
                       1745.923077 27119.846154 1001.700000
      England
                                                              63.307692
      Northern Ireland 1810.000000 18438.000000
                                                 369.200000
                                                             200.000000
                       1691.428571 19563.142857
      Scotland
                                                 410.471429 200.571429
                       1901.500000 23259.000000
                                                 644.800000 221.000000
      Wales
```

Groups support column indexing. If we want to only compute the total number of students for each country in our sample, we can do this as follows:

There are numerous routines available to aggregate grouped data, for example:

- mean(), sum(): averages and sums over numerical items within groups.
- std(), var(): within-group std. dev. and variances
- size(): group sizes
- first(), last(): first and last elements in each group
- min(), max(): minimum and maximum elements within a group

Examples:

```
[24]: groups.size() # return number of elements in each group
```

```
[24]: Country
      England
                         13
      Northern Ireland
                          1
                          7
      Scotland
                          2
      Wales
      dtype: int64
[25]: groups.first()
                          # return first element in each group

                                                                              191
```

We can create custom aggregation routines by calling agg() or aggregate() on the grouped object. To illustrate, we count the number of universities in each country that have more than 20,000 students:

Note that we called agg() only on the column Students, otherwise the function would be applied to every column separately, which is not what we want.

The most flexible aggregate function is apply(), which calls the given function with the entire group-specific subset of data (including all columns) and glues together the results.

For example, if we want to compute the average budget per student (in pounds), we can do this as follows:

We couldn't have done this with agg () since agg () never gets to see the entire chunk of data but only one column at a time.

This section provided only a first look at pandas's "split-apply-combine" functionality implemented via groupby. See the official documentation for more details.

1.6 Visualisation

We covered plotting with Matplotlib in earlier units. Pandas itself implements some convenience wrappers around Matplotlib plotting routines which allow us to quickly inspect data stored in DataFrames. We can of course alternatively extract the numerical data and pass it to Matplotlib's routines instead.

For example, to plot student numbers as a bar chart, we can directly use Pandas:

```
[28]: import pandas as pd

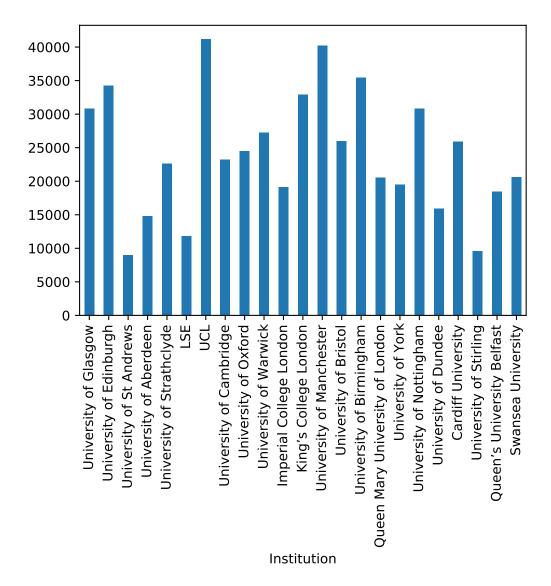

df = pd.read_csv('.../data/universities.csv', sep=';')

# set institution as label so they automatically show up in plot

df2 = df.set_index(keys=['Institution'])

df2['Students'].plot(kind='bar')
```

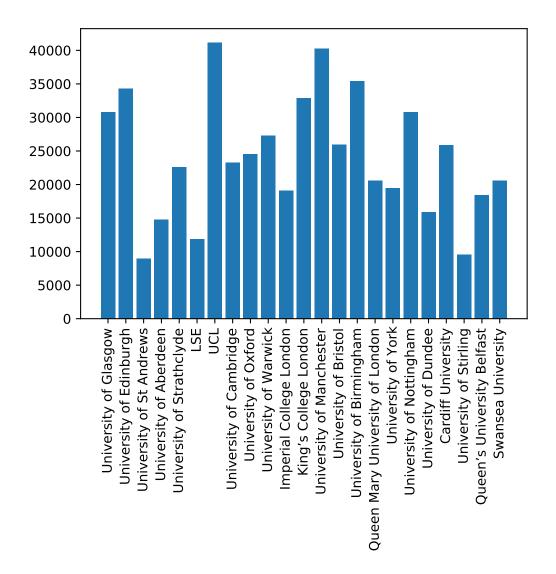

[28]: <AxesSubplot:xlabel='Institution'>

Alternatively, we can construct the graph using Matplotlib ourselves:

```
[29]: import matplotlib.pyplot as plt

labels = df['Institution'].to_list()  # labels as list
values = df['Students'].to_numpy()  # data as NumPy array
plt.bar(labels, values)
plt.tick_params(axis='x', labelrotation=90)
```

Sometimes Matplotlib's routines directly work with pandas's data structures, sometimes they don't. In cases where they don't, we can convert a DataFrame or Series object to a NumPy array using the to_numpy() method, and convert a Series to a Python list using to_list(), as illustrated in the example above.

To plot timeseries-like data, we can use the plot () method, which optionally accepts arguments to specify which columns should be used for the x-axis and which for the y-axis:

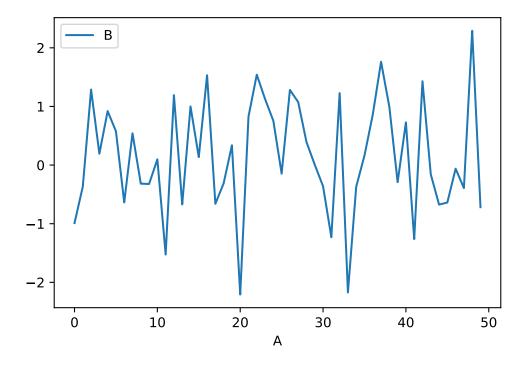

```
[30]: import numpy as np
import pandas as pd

# Instantiate RNG
rng = np.random.default_rng(123)

# Create pandas DataFrame
nobs = 50
df = pd.DataFrame({'A': np.arange(nobs), 'B': rng.normal(size=nobs)})

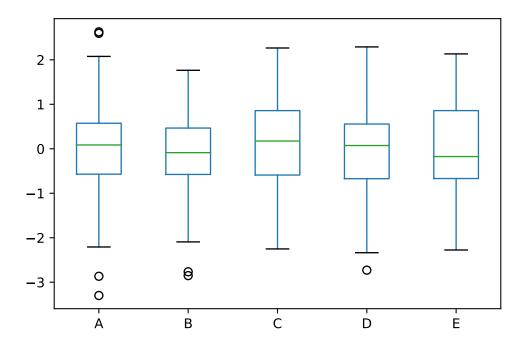

df.plot(x='A', y='B') # plot A on x-axis, B on y-axis
```

[30]: <AxesSubplot:xlabel='A'>

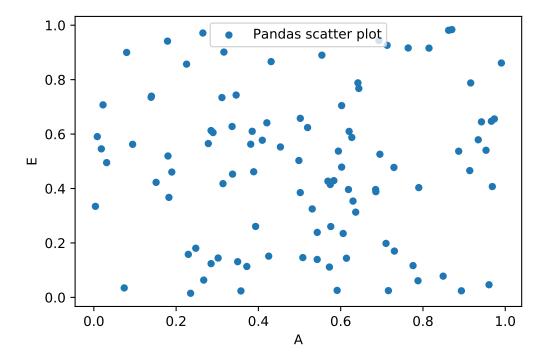

To quickly generate some descriptive statistics, we can use the built-in box plot:

[31]: <AxesSubplot:>

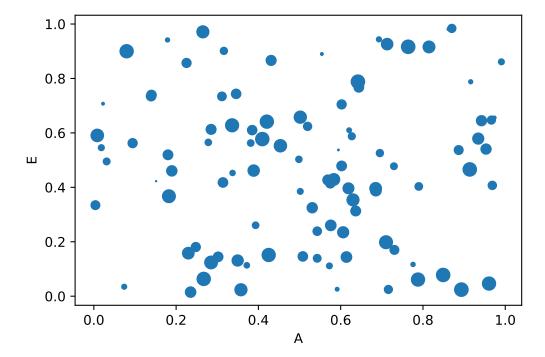

Similarly, we can generate scatter plots, plotting one column against another:

[32]: <AxesSubplot:xlabel='A', ylabel='E'>

```
[33]: # We can even use a column to specify the dot size! df.plot.scatter(x='A', y='E', s=df['B']*100.0)
```

[33]: <AxesSubplot:xlabel='A', ylabel='E'>

In general, the wrappers implemented in Pandas are useful to get an idea how the data looks like. For reusable code or more complex graphs, we'll usually want to directly use Matplotlib and pass the data converted to NumPy arrays.
